

FACTORS PREDICTING HIV AWARENESS IN UGANDA

Findings

The data used for this project is Secondary data that was downloaded from the World bank database. The analysis provides a descriptive picture of HIV/AIDS awareness, testing, access to information, and knowledge across different age groups and genders. The results show that the selected indicators vary across age groups, suggesting that HIV-related awareness and knowledge are not distributed uniformly within the population. The comparison of the six indicators also shows differences in their average values, indicating that being exposed to HIV/AIDS information does not necessarily correspond to the same level of comprehensive knowledge or acceptance of HIV-related discussions. The gender comparison further highlights differences in the values recorded for indicators relating to men and women.

Limitations

However, the analysis has several limitations. Firstly, the six indicators measure different aspects of HIV/AIDS awareness and knowledge, so calculating an overall average across them should be interpreted cautiously. Secondly, the analysis is descriptive and does not establish causal relationships between HIV/AIDS information, testing, and comprehensive knowledge. Thirdly, the dataset is based on secondary data, meaning that the analysis is limited to the variables and categories available in the source dataset.

In addition, the age groups weren't defined properly which prompted me to create age groups that could easily be understood by different stakeholders. Furthermore, gender had many missing values which prompted me to clean this data by dropping all missing variables and analysing those that remained. Finally, the analysis does not yet use statistical or machine-learning models to determine which factors are most important in predicting comprehensive HIV/AIDS knowledge. Therefore, the findings provide useful initial patterns but should not be interpreted as evidence of cause and effect.
